Abstract

One of the tightest known protein–protein interactions in biology is that between members of the ribonuclease A superfamily and the ribonuclease inhibitor protein (RI). Some members of this superfamily are able to kill cancer cells, and the ability to evade RI is a major determinant of whether a ribonuclease will be cytotoxic. The archetypal cytotoxic ribonuclease, onconase (ONC), is in late-stage clinical trials for the treatment of malignant mesothelioma. We present here the first measurement of the inhibition of the ribonucleolytic activity of ONC by RI. This inhibition occurs with $K_i = 0.15 \mu M$ in a solution of low salt concentration.

Protein–protein interactions are prevalent in biological systems. Proper functioning of organisms relies on the formation of complexes, such as those between antibodies and antigens, growth factors and receptors, and enzymes and regulators. These interactions have evolved the necessary affinity for their function, as well as the ability to dissociate within a practical timeframe. The theoretical upper limit for the encounter of two proteins in aqueous solution has been estimated to be $\sim 10^6 M^{-1} s^{-1}$ [1;2]. This rate can be increased via electrostatic steering [3–7], as has been observed with barnase and barstar [8], cytochrome c and cytochrome c peroxidase [9], and thrombin and hirudin [10].

The association rate for the complex formed between secreted members of the bovine pancreatic ribonuclease (RNase A) superfamily and the cytosolic ribonuclease inhibitor protein (RI) is high ($k_a = 10^8 M^{-1} s^{-1}$ for RNase A and human RI) [11]. The related dissociation rate is low, giving an equilibrium dissociation constants in the femtomolar range ($K_d = 0.29 fM$ for the complex between RI and human pancreatic ribonuclease (RNase 1); Figures 1A and 1B) [7]. This high stability has apparently evolved to protect cells against the adventitious invasion of ribonucleases [12]. Indeed, RNase A and RNase 1 variants that evade RI are cytotoxic [7; 13–16].

The interface between RI and ribonucleases contains a higher percentage of charged residues than that typically present in protein-protein complexes [15;17], suggesting a role for electrostatics in complex stability. RI is highly anionic, with an isoelectric point of $pI = 4.7$ [18], and pancreatic-type ribonucleases are highly cationic. Decreasing the net charge of RNase 1 leads to a decrease in affinity for RI [19]. RI is typically purified by RNase A-affinity

chromatography, and eluted from the resin with 3 M NaCl [20]. In addition, the inhibition constant ($K_i$) for the complex between placental RI and RNase A increases by more than four orders of magnitude from 0.1–1.0 M NaCl [21].

Onconase (ONC) [22;23] is a homologue of RNase A from the Northern leopard frog *Rana pipiens* [24]. Unlike RNase A and RNase 1, ONC is naturally toxic to cancer cells [24] and is currently in Phase IIIb clinical trials for the treatment of malignant mesothelioma [25]. Its cytotoxic activity is ascribed primarily to its low affinity for RI [16;26;27], which is not detectable in assays at physiological salt concentration [28;29] and has been estimated to be $K_i \geq 1 \mu$M [27]. ONC (104 residues) is markedly smaller than either RNase A (124) or RNase 1 (128). The likely absence of deleterious steric interactions in an RI-ONC complex suggests that ONC should have some intrinsic affinity for RI.

The interaction between RI and ribonucleases is typically measured in solutions of physiological salt concentration, such as PBS [28;29]. In aqueous solutions containing salts, ions interact with charged proteins such as RI and ribonucleases preferentially, with cations primarily interacting with anionic surfaces and anions with cationic surfaces. This phenomenon leads to an unequal distribution of ions in the solution; a higher local concentration of ions is present in the vicinity of the proteins than in the bulk solution [30]. When RI binds to ribonucleases, there is a decrease of 2583–3438 Å$^2$ in the surface area that is exposed to the surrounding solution [16]. This burial results in the release of the ions that were interacting with the surface of the proteins in the interfacial region, and an accompanying increase in the entropy of the system. In solutions of lower salt concentration, the concentration gradient of ions between the bulk water and local water is increased further, increasing the entropy of binding and thus making binding more favorable [30].

Like its homologues, ONC is a highly cationic protein (pI $>9.5$, Figure 1C) [31]. Considering the high charge density of ONC and RI and the large amount of surface area buried in RI-ribonuclease complexes, we reasoned that RI might inhibit ONC in solutions of low salt concentration. Here, we report the first measurement of such an interaction.

**Materials and methods**

**Materials**

*Escherichia coli* BL21(DE3) cells and pET22b(+) plasmid were from Novagen (Madison, WI). Enzymes were obtained from Promega (Madison, WI). Bovine serum albumin (BSA) was obtained as a 20 mg/mL solution (Sigma–Aldrich, St. Louis, MO; product #B8667). 6-Carboxyfluorescein–dArUdGdA–6-carboxytetramethylrhodamine (6-FAM–dArUdGdA–6-TAMRA) [32;33] was obtained from Integrated DNA Technologies (Coralville, IA). Costar 96-well NBS microtiter plates were from Corning Life Sciences (Acton, MA). MES buffer (Sigma–Aldrich) was purified by anion-exchange chromatography to remove oligo (vinylsulfonic acid) (OVS), a potent inhibitor of ribonucleases [34]. All other chemicals used were of commercial grade or better, and were used without further purification.

**Instrumentation**

Molecular mass was measured by matrix-assisted laser desorption/ionization time-of-flight (MALDI–TOF) mass spectroscopy using a Voyager-DE-PRO Biospectrometry Workstation (Applied Biosystems, Foster City, CA) at the University of Wisconsin–Madison Biophysics Instrumentation Facility. The fluorescence intensity in microtiter plates was recorded with a Perkin–Elmer EnVision 2100 plate reader equipped with a FITC filter set (excitation at 485 nm with 14-nm bandwidth; emission at 535 nm with a 25-nm bandwidth; dichroic mirror cutoff at 505 nm) at the W.M. Keck Center for Chemical Genomics.
Purification of ribonuclease inhibitor and ribonucleases

Human RI [7] and RNase A [13] were purified as described previously. ONC was purified as described previously [13], with the following exceptions. ONC was refolded overnight at room temperature after slow dilution (by 10-fold) into 0.10 M Tris–HCl buffer, pH 8.0, containing NaCl (0.10 M), reduced glutathione (3.0 mM), and oxidized glutathione (0.6 mM). After concentration by ultrafiltration, samples were dialyzed overnight against 50 mM sodium acetate buffer, pH 5.0, containing NaCl (0.10 M), and purified by FPLC using Mono S cation-exchange resin (Pharmacia, Uppsala, Sweden). ONC was eluted from the resin with a linear gradient of NaCl (0.15–0.30 M). Protein concentrations were determined by UV spectroscopy using extinction coefficients of $\varepsilon_{280} = 0.88$ (mg/mL)$^{-1}$·cm$^{-1}$ for RI [20], $\varepsilon_{278} = 0.72$ (mg/mL)$^{-1}$·cm$^{-1}$ for RNase A, and $\varepsilon_{250} = 0.87$ (mg/mL)$^{-1}$·cm$^{-1}$ for ONC [13]. The molecular masses of RNase A and ONC were confirmed by MALDI–TOF mass spectrometry.

Determination of $K_i$ value for ONC

A serial dilution (12.5 μM→96 pM; 2×) of RI in MES–NaOH buffer (20 mM), pH 6.0, containing DTT (5 mM), and BSA (0.1%) was prepared. A 50-μL aliquot of this serial dilution was added to the wells of a 96-well plate. A solution (50-μL) of ONC (100 nM; 2×) in MES–NaOH buffer (20 mM), pH 6.0, containing DTT (5 mM), and BSA (0.1% w/v) was prepared in Eppendorf Protein LoBind Tubes (Fisher Scientific) and added to each well. The negative control contained no RI and the positive control contained excess RNase A (550 μM). A hypersensitive fluorogenic substrate, 6-FAM–dArUdGdA–6-TAMRA (100 nM) [32;33], was added to each well and fluorescence intensity was measured at 25 °C every 30 s over a 5-min period. Data were fitted using nonlinear regression to a dose-response curve using Prism 4 for Macintosh.

Results and discussion

Nonspecific interactions can occur between proteins in solutions of low salt concentration. These interactions can bring together residues that are not at a biologically relevant interface between the proteins. Such weak interactions are screened in solutions of physiological salt concentration [5;35]. To avoid detecting such nonspecific interactions between RI and ONC, we used an activity-based assay to detect binding, measuring the ability of RI to inhibit the ribonucleolytic activity of ONC. These assays were performed at pH 6.0, which is close to the pH-optimum for catalysis by ONC [36]. We found that RI does inhibit the enzymatic activity of ONC under these conditions, and that the value of $K_i = (0.15 \pm 0.05)$ μM (Figure 2). We conclude that there is no obstacle that precludes the formation of an RI-ONC complex. Instead, this complex is merely disfavored relative to those of RI and RNase A or RNase 1.

The ribonuclease A superfamily is a vertebrate-specific family that is evolving rapidly [37;38]. Ribonucleases and inhibitors from different classes do not interact [39], and the intraspecies complexes are more stable and form more rapidly than do interspecies complexes [40]. The framework for RI-binding is in place in ONC (i.e., the molecular shape and charge distribution; Figures 1B and 1C), but the individual residues that closely interact with RI in other ribonucleases are largely absent in ONC [16;27]. These factors combine to allow ONC to interact with RI in a solution of low salt concentration, but not at physiological salt concentrations. Ongoing work in our laboratory is aimed at isolating an RI homologue from Rana pipiens. The measurement of its affinity for amphibian and mammalian ribonucleases will inform our understanding of the evolution of these interesting and important binding partners.
